Abstract

Predicting how populations will respond to ocean change across generations is critical to effective conservation of marine species. One emerging factor is the influence of parental exposures on offspring phenotype, known as intergenerational carryover effects. Parental exposure may deliver beneficial or detrimental characteristics to offspring that can influence larval recruitment patterns, thus shaping how populations and community structure respond to ocean change. Impacts of adult exposure to elevated winter temperature and pCO_2 on reproduction and offspring viability were examined in the Olympia oyster (*Ostrea lurida*) using three populations of adult, hatchery-reared *O. lurida,* plus an additional cohort spawned from one of the populations. Oysters were sequentially exposed to elevated temperature (+4°C, at 10°C), followed by elevated pCO_2 (+2204 µatm, at 3045 µatm) during winter months. Male gametes were more developed after elevated temperature exposure and less developed after high pCO_2 exposure, but there was no impact on female gametes or sex ratios. Oysters previously exposed to elevated winter temperature released larvae earlier, regardless of pCO_2 exposure. Those exposed to elevated winter temperature as a sole treatment released more larvae on a daily basis, but when also exposed to high pCO_2 there was no effect. These combined results indicate that elevated winter temperature accelerates *O. lurida* spermatogenesis, resulting in earlier larval release and increased production, with elevated pCO_2 exposure negating effects of elevated temperature. Altered recruitment patterns may therefore follow warmer winters due to precocious spawning, but these effects may be masked by coincidental high pCO_2. Offspring were reared in common conditions for one year, then deployed for three months in four estuarine bays with distinct environmental conditions. Offspring of parents exposed to elevated pCO_2 had

higher survival rates in two of the four bays. This carryover effect demonstrates that parental conditions can have substantial ecologically relevant impacts that should be considered when predicting impacts of environmental change. Furthermore, Olympia oysters may be more resilient in certain environments when progenitors are pre-conditioned in stressful conditions. Combined with other recent studies, our work suggests that the Olympia may be more equipped than other oysters for the challenge of a changing ocean.

Keywords: Ostrea lurida, acidification, pH, warming, winter, reproduction, phenology, intergenerational, transgenerational, climate change

Introduction

The repercussions of ocean warming and acidification on marine invertebrate physiology are complex, but significant recent advances indicate that larval stages of marine taxa are particularly vulnerable (Byrne & Przeslawski, 2013; Kurihara, 2008; Przeslawski, Byrne, & Mellin, 2015). Understanding how shifting conditions will influence larval recruitment patterns is critical to predicting changing population dynamics, and thus community structure. One emerging consideration is whether larval stages benefit from ancestral exposures, based on evidence that memory of environmental stressors can be transferred between generations through non-genetic inheritance (reviewed in Perez & Lehner, 2019; Donelson *et al.* 2018; Eirin-Lopez & Putnam, 2019; Ross, Parker, & Byrne, 2016). Beneficial, or positive, carryover effects may be important acclimatory mechanisms for marine organisms facing rapid change, particularly those that evolved in dynamic environments like estuaries and the intertidal (Donelson, Salinas, Munday, & Shama, 2018; Gavery & Roberts, 2014). These carryover effects are defined as

49 transgenerational when they persist in generations that were never directly exposed.
50 Intergenerational, or parental, effects may be due to direct exposure as germ cells (Perez &
51 Lehner, 2019). Trans- and intergenerational carryover effects are increasingly reported across
52 marine phyla, including Cnidaria (*e.g.* Putnam & Gates, 2015), Echinodermata (*e.g.* Clark *et al.*,
53 2019), Mollusca (*e.g.* Parker *et al.* 2015), Arthropoda (*e.g.* Thor & Dupont, 2015), and Chordata
54 (Review: Munday 2014).
55 A foundational series of studies on the Sydney rock oyster (*Saccostrea glomerata*)
56 provide strong evidence for intergenerational carryover effects in bivalves, an ecologically and
57 economically important group of taxa (Dumbauld, Ruesink & Rumrill, 2009). Adult *S.*
58 *glomerata* exposed to high pCO_2 produced larger larvae that were less sensitive to high pCO_2,
59 and the effect persisted in the successive generation (Parker *et al.*, 2012, 2015). In the presence
60 of secondary stressors, however, parental high pCO_2 exposure rendered larvae more sensitive
61 (Parker *et al.*, 2017). Intergenerational carryover effects are increasingly documented in larvae
62 across other bivalve species, and are beneficial in the mussels *Mytilus chilensis* (Diaz *et al*.,
63 2018) and *Mytilus edulis* (but not juveniles) (Kong *et al*., 2019; Thomsen *et al*., 2017), and
64 detrimental in the clam *Mercenaria mercenaria*, the scallop *Argopecten irradians* (Griffith &
65 Gobler, 2017), and the oyster *Crassostrea gigas* (Venkataraman, Spencer, & Roberts, 2019).
66 These preliminary studies provide strong evidence for intergenerational carryover effects
67 in bivalves, but the body of work is still narrow in scope. Nearly all studies have exposed parents
68 to stressors during denovo gamete formation (gametogenesis). For many temperate bivalve
69 species, this occurs seasonally in the spring (Bayne, 1976). Yet, challenging periods of
70 acidification and warming can occur during other times of the year (Evans, Hales, & Strutton,
71 2013; Joesoef, Huang, Gao, & Cai, 2015; McGrath, McGovern, Gregory, & Cave, 2019). The

most corrosive carbonate environment in the Puget Sound estuary in Washington State, for example, commonly occurs in the winter when many species are reproductively inactive, while favorable conditions are in the spring when gametogenesis coincides with phytoplankton blooms (Pelletier, Roberts, Keyzers, & Alin, 2018). Thus, adult exposure to severely corrosive conditions during gametogenesis may not represent the natural estuarine system. To our knowledge, only one study has assessed carryover effects of exposure to acidification before reproductive conditioning in a bivalve, the oyster *C. gigas*, and found negative maternal carryover effects on larval survival (Venkataraman, Spencer, & Roberts, 2019), indicating that pre-gametogenic exposure also matters. No studies have yet attempted to examine intergenerational carryover effects of combined winter warming and acidification in bivalves.

To best predict whether intergenerational carryover effects will be beneficial or detrimental, it is also crucial to understand how warming and acidification will impact fertility and reproductive phenology. Temperature is a major driver of bivalve reproduction, and modulates gametogenesis (Joyce, Holthuis, Charrier, & Lindegarth, 2013; Maneiro, Pérez-Parallé, Pazos, Silva, & Sánchez, 2016; Oates, 2013), influences sex determination (Santerre *et al.*, 2013) and, in many species, triggers spawning (Fabioux, Huvet, Le Souchu, Le Pennec, & Pouvreau, 2005) (alongside other factors such as photoperiod, nutrition, lunar/tidal phases). Year-round warming may result in unexpected impacts to larval competency resulting from changes to reproduction. For instance, some temperate bivalve species have a thermal threshold for gametogenesis and enter a period of reproductive inactivity, or "quiescence", which is believed necessary for successive spawning (Giese, 1959; Hopkins, 1937; Loosanoff, 1942). Warmer winters brought on by global climate change (IPCC, 2013, 2019) may therefore shift species' reproductive cycles to begin earlier, or eliminate seasonality altogether, resulting in

poorly provisioned or ill-timed larvae (Chevillot *et al.*, 2017). Such impacts were clearly demonstrated using a long-term dataset (1973-2001) of estuarine clam *Macoma balthica* reproduction and temperature. Mild winters and earlier springs resulted in low fecundity, earlier spawning, and poor recruitment, which was largely explained by a phenological mismatch between spawning and peak phytoplankton blooms (Philippart *et al*., 2003). The impacts of winter acidification on estuarine bivalve reproduction are less predictable. The few studies to date show that high pCO_2 delays gametogenesis in the oysters *Crassostrea virginica* and *S. glomerata* (Boulais *et al*., 2017; Parker *et al*., 2018), but both studies exposed oysters during gametogenesis. Acidification during the winter months could increase energetic requirements (Sokolova, Frederich, Bagwe, Lannig, & Sukhotin, 2012), and deplete glycogen reserves that are later utilized for gametogenesis in the spring (Mathieu & Lubet, 1993), but this hypothesis has yet to be tested.

The purpose of this study was to assess whether warmer, less alkaline winters will affect fecundity and offspring viability in the Olympia oyster, *Ostrea lurida*. The Olympia is native to the Pacific coast of North America (McGraw, 2009). Overharvest and pollution devastated populations in the early 1900s, and today 2-5% of historic beds remain (Blake & Bradbury, 2012; Polson & Zacherl, 2009). Restoration efforts are afoot, but *O. lurida* populations continue to struggle, and may be further challenged by changing conditions (Barton, Hales, Waldbusser, Langdon, & Feely, 2012; Feely, Klinger, Newton, & Chadsey, 2012; Feely, Sabine, Hernandez-Ayon, Ianson, & Hales, 2008). For instance, large interannual variability in larval recruitment and frequent recruitment failures were recently reported (Wasson *et al*., 2016; Kimbro, White & Grosholz, 2019). This variability is presumably related to inconsistent spawning success, larval survival, and retention, and governed predominantly by local conditions (Kimbro, White &

118 Grosholz, 2019). It is unknown how the intensity, timing, and duration of local environmental
119 conditions can predict recruitment failure (Wasson *et al*., 2016). If winter conditions
120 significantly influence recruitment through direct changes to adult reproductive capacity or
121 timing, or indirect changes through parental carryover effects, population densities and
122 distributions will inevitably shift with conditions.

123 Another consideration in this study was the genetic composition of test organisms. *Ostrea*
124 *lurida* exhibits varying phenotypes among distinct populations (Silliman, 2019), which can
125 influence their sensitivity to environmental stressors (Bible & Sanford, 2016; Bible, Evans &
126 Sanford, 2019). Indeed, the two groups to measure the response of *O. lurida* larvae to ocean
127 acidification found contrasting results – no effect (Waldbusser *et al*., 2016), and slower growth
128 (Hettinger *et al.*, 2012, 2013) – possibly a result of local adaptation. The source population used
129 for experimental studies may therefore be a critical factor influencing climate-related findings.
130 Furthermore, testing genetically diverse organisms could reveal cryptic genetic variation, alleles
131 that confer stress resilience only under certain settings (Paaby & Rockman, 2014; Bitter *et al.*,
132 *preprint*), which has implications for how wild populations are restored. Therefore, we tested
133 three phenotypically distinct Puget Sound populations (Heare, Blake, Davis, Vadopalas, &
134 Roberts, 2017; Silliman, Bowyer, & Roberts, 2018), which were hatchery-reared in common
135 conditions to adulthood, to account for intraspecific variation while controlling for within-
136 generation carryover effects (Hettinger *et al.*, 2012, 2013).

137 Our study is the first to assess the combined effects of elevated winter temperature and
138 pCO_2 on reproduction, and to explore intergenerational carryover in an *Ostrea* spp. We exposed
139 adult *O. lurida* to elevated temperature (+4°C), followed by elevated pCO_2 (+2204 µatm, -0.51
140 pH). Gonad development, reproductive timing, and fecundity were assessed for the adults in the

laboratory, and offspring performance was assessed in the field. Elevated winter temperature was expected to impede gametogenic quiescence, presumably a critical annual event, subsequently reducing larval production. This prediction was in part based on observations of low larval yields in an *O. lurida* restoration hatchery (Ryan Crim, *unpublished*) following the winter 2016 marine heat wave in the Northeast Pacific Ocean (Gentemann, Fewings, & García-Reyes, 2017). Similarly, we predicted that high pCO_2 exposure would result in negative impacts due to increased energy requirements for calcification and cellular maintenance. Finally, we predicted that negative impacts would be amplified upon exposure to both conditions. By assessing the effects of winter warming and acidification on reproduction and offspring viability in multiple Olympia oyster populations, we provide an ecologically relevant picture of how the species will respond to ocean change.

Methods

Adult oyster temperature and pCO_2 exposures

Four cohorts of adult *Ostrea lurida* were used in this study. Three of the cohorts were first-generation hatchery-produced (F1) oysters (32.1 ± 5.0 mm), all hatched in Puget Sound (Port Gamble Bay) in 2013 (Heare *et al*., 2017). The broodstock used to produce these F1 oysters were wild, harvested from Fidalgo Bay in North Puget Sound (F), Dabob Bay in Hood Canal (D), and Oyster Bay in South Puget Sound (O-1) (O in Figure 1). These populations are considered phenotypically distinct subpopulations (Heare *et al.*, 2017; White, Vadopalas, Silliman, & Roberts, 2017). The fourth cohort (O-2, 21.9 ± 3.3 mm) was second-generation, hatchery-produced in 2015 from the aforementioned Oyster Bay F1 cohort, from a single larval release pulse and thus likely one family (Silliman, Bowyer, & Roberts, 2018). The O-2 cohort was

included to examine whether reproductive and offspring traits were consistent across generations of a population, with the O-2 cohort being closely related to each other (siblings) and 2 years younger than the other cohorts. Prior to the experiment, all oysters were maintained in pearl nets in Clam Bay (C) for a minimum of 500 days.

Temperature treatment

Oysters were moved from Clam Bay (C) to the Kenneth K. Chew Center for Shellfish Research and Restoration for the temperature and pCO_2 experiments. Oysters were held in one of two temperature regimes (6.1±0.2°C and 10.2±0.5°C) for 60 days beginning December 6, 2016 (Figure 2). The temperatures correspond to historic local winter temperature (6°C) in Clam Bay, and anomalously warm winter temperature (10°C) as experienced during 2014-2016 (Gentemann *et al.*, 2017). For the temperature exposure, oysters from each cohort (100 for O-1 and F cohorts, 60 for D, and 300 for O-2) were divided into four bags, two bags per temperature, in two flow-through experimental tanks (50L - 1.2-L/min). Temperature in the 6°C treatment was maintained using an aquarium chiller, and unchilled water was used for the 10°C treatment. Temperatures were recorded continuously with water temperature data loggers.

High pCO_2 treatment

A differential pCO_2 exposure was carried out after the temperature treatment ended. Following a 10-day gradual temperature increase for the 6°C treatment to 10°C, oysters were further divided and held at ambient pCO_2 (841±85 µatm, pH 7.82±0.02) or high pCO_2 (3045±488 µatm, pH 7.31 ± 0.02) for 52 days (February 16 to April 8, 2017, Figure 2). Animals were housed in six flow-through tanks (50-L - 1.2-L/min), with three replicate tanks per pCO_2 treatment and oyster

184 cohort. High pCO_2 treated water was prepared using CO_2 injection. Filtered seawater (1µm) first
185 recirculated through a reservoir (1,610-L) with a degassing column to equilibrate with the
186 atmosphere, then flowed into treatment reservoirs (757-L) recirculating through venturi injectors.
187 Durafet pH sensors and a Dual Input Analytical Analyzer monitored pH in treatment reservoirs
188 with readings every 180 seconds. Using solenoid valves, CO_2 gas was injected through lines at
189 15 psi in 0.4 second pulses if pH exceeded the 7.22 set point. Water pH was continuously
190 monitored in experimental tanks using Durafet pH sensors, and temperature (10.4 ± 0.4°C) was
191 measured using water temperature data loggers. Twice weekly, water samples (1-L) were
192 collected from experimental tanks, and temperature (°C), salinity (PSU), and pH (mV, converted
193 to pH_T) were measured immediately using a digital thermometer, conductivity meter, and pH
194 electrode, respectively. Simultaneously, discrete water samples (120-mL) were collected in
195 duplicate from experimental tanks and preserved with HgCl (50-µL) for later total alkalinity
196 measurements using a titrator. Standard pH curves were generated on each sampling day prior to
197 pH measurements using TRIS buffer prepared in-house at five temperatures (Appendix S1:
198 Section S1). Using the `seacarb` library in R, pCO_2, dissolved organic carbon (DIC), calcite
199 saturation ($\Omega_{calcite}$), and aragonite saturation ($\Omega_{aragonite}$) were calculated for days 5, 33, and 48
200 (Appendix S1: Table S1).
201 During both temperature and pCO_2 treatments, all oysters were fed from a shared algae
202 header tank daily with Shellfish Diet 1800® (300-500-mL, Reed Mariculture) diluted in ambient
203 pCO_2 seawater (200-L, Helm & Bourne, 2004), dosed continuously with metering pumps.
204 Experimental, reservoir, and algae tanks were drained and cleaned, and oysters were monitored
205 for mortality and rotated within the experimental system twice weekly.
206

Adult reproductive development

A subset of oysters was sampled for gamete stage and dominant sex immediately before and after pCO_2 treatments (Figure 2) to capture developmental differences among treatments. Puget Sound *O. lurida* reportedly enter reproductive quiescence and resorb residual gametes when temperatures are below 12.5°C (Hopkins 1936, 1937), however recent evidence of low-temperature brooding in Puget Sound (10.5°C, Barber *et al*. 2016) suggests that reproductive activity may occur during warm winters. Therefore, gonad tissue was sampled to estimate the following: 1) whether residual gametes were resorbed or developed during winter treatments; 2) whether temperature and pCO_2 influenced winter activity; 3) if male and female gametes responded similarly; and 4) if gonad responses correspond with fecundity. Prior to pCO_2 exposure, 15 oysters were sampled from O-1, O-2, and F cohorts, and 9 from the D cohort. After pCO_2 exposure, 9, 6, and 15 oysters were sampled from each treatment for O-1/F, D, and O-2 cohorts, respectively (distributed equally among replicates tanks). Whole visceral mass was excised and preserved in histology cassettes using the PAXgene Tissue FIX System, then processed for gonad analysis by Diagnostic Pathology Medical Group, Inc. (Sacramento, CA).

Adult gonad samples were assigned sex and stage using designations adapted from (da Silva, Fuentes, & Villalba, 2009) (Appendix S1: Tables S2 & S3). Sex was assigned as indeterminate (I), male (M), hermaphroditic primarily-male (HPM), hermaphroditic (H), hermaphroditic primarily-female (HPF), and female (F). Gonad sex was collapsed into simplified male and female designations for statistical analyses (hermaphroditic-primarily male = male, hermaphroditic-primarily female = female). For stage assignment, male and female gametes were assigned separately due to the high frequency of hermaphroditism (50.8%). Dominant gonad stage was then assigned based on the sex assignment. The da Silva gonad stages were

applied for early gametogenesis (stage 1), advanced (stage 2), and ripe (stage 3). Departures from da Silva's stage 0, stage 4 (partially spawned), and stage 5 (fully spawned/resorbing) were as follows: stage 0 in this study represents empty follicles, or no presence of male or female gonad tissue; stage 4 represents both spawned and resorbing gonad; this method did not include a separate stage 5, due to the very high frequency of residual gametes, and no distinct partially spawned oysters (for gonad images see Appendix S1: Fig. S2 and Spencer *et al.* 2019).

Treatment effects on gonad tissue were assessed for all cohorts combined in 4 gonad metrics: 1) gonad stage of dominant sex, 2) male gonad tissue when present, 3) female gonad tissue when present, and 4) gonad sex-collapsed (Chi-square test of independence). To assess the effects of elevated winter temperature alone, gonad metrics were compared between 6°C and 10°C treatments prior to pCO_2 treatment. To determine the effect of pCO_2 exposure, gonad metrics were compared between ambient and high pCO_2 after 52 days in pCO_2 treatments, including temperature interaction effects. To estimate whether gonad changed during pCO_2 treatment, metrics were compared before and after ambient and high pCO_2 treatments, including temperature interaction effects. P-values were estimated using Monte-Carlo simulations with 1,000 permutations, and corrected using the Benjamini & Hochberg method and α=0.05 (Benjamini & Hochberg, 1995).

Larval production

Following pCO_2 exposure, adult oysters were spawned to assess impacts of winter treatment on larval production timing and magnitude. Beginning on April 11, 2017 (Figure 2), oysters were reproductively conditioned by raising temperatures gradually (~1°C/day) to 18.1 ± 0.1°C and fed live algae cocktail at 66,000 ± 12,000 cells/mL. Oysters spawned in the hatchery for 90 days

253 volitionally, i.e. naturally releasing gametes without chemical or physical manipulation. Six
254 spawning tanks were used for each temperature x pCO_2 treatment: 6°C-high pCO_2, 6°C-ambient
255 pCO_2, 10°C-high pCO_2, and 10°C-ambient pCO_2. Within the six tanks per treatment, two
256 spawning tanks contained the F cohort (14-17 oysters), two tanks the O-1 cohort (14-17 oysters),
257 one tank the D cohort (9-16 oysters), and one tank the O-2 cohort (111-126 oysters). More O-2
258 oysters were used due to their small size. Olympia oysters release sperm, but have internal
259 fertilization and release veliger larvae following a ~2 week brooding period (Coe ,1931;
260 Hopkins, 1937). Therefore, production was assessed by collecting veliger larvae upon maternal
261 release. Spawning tank outflow was collected in 7.5-L buckets using 100 µm screens made from
262 15.25 cm polyvinyl chloride rings and 100 µm nylon mesh.
263 Larval collection was assessed for differences in spawn timing and fecundity. Larvae,
264 first observed on May 11, 2017 (Figure 2), were collected from each spawning tank every one or
265 two days for 60 days. The number of larvae released was estimated by counting and averaging
266 triplicate subsamples of larvae homogenized in seawater. The following summary statistics were
267 compared between temperature x pCO_2 treatments: total larvae released across the 90-day
268 period, average number of larvae collected on a daily basis (excluding days where no larvae were
269 released), maximum larvae released in one day, date of first release, date of maximum release,
270 and number of substantial release days (greater than 10,000 larvae). The total and daily release
271 values were normalized by the number of broodstock * average broodstock height (cm), which
272 can impact fecundity. Distributions were assessed using `qqp` in the `car` package for R (Fox &
273 Weisberg, 2011), and log-transformed to meet normal distribution assumptions, if necessary.
274 Differences between treatments were assessed using linear regression and Three-Way ANOVA
275 (cohort was included as a covariate) with backwards deletion to determine the most

parsimonious models. Tukey Honest Significant Differences were obtained using `TukeyHSD` to assess pairwise comparisons (R Core Team, 2016). Dates of peak larval release were also estimated for each pCO_2 x temperature treatment by smoothing using locally weighted regression, with `geom_smooth` in the ggplot package (Wickham, 2017), with span=0.3 and degree=1.

Offspring survival in a natural setting

To assess potential carryover effects of parental pCO_2 exposure, offspring from parents in 6ºC-ambient pCO_2 and 6ºC-high pCO_2 treatments were reared then deployed in the natural environment. To focus on the effect of parental pCO_2 exposure, only offspring from 6ºC parents were tested in the field (Figure 2). Larvae were collected between May 19 and June 22, 2017, separated by parental pCO_2 exposure and cohort, and reared in common conditions for approximately 1 year (Figure 2; for rearing methods see Appendix S1: Section S6). On June 12, 2018 the juveniles were placed in four bays in Puget Sound — Fidalgo Bay, Port Gamble Bay, Skokomish River Delta, and Case Inlet — with two sites per bay, for a total of eight locations (Figure 1). Autonomous sensors collected continuous water quality data at each location for pH, salinity (via conductivity), dissolved oxygen, temperature, and chlorophyll. For the F/D and O-1/O-2 cohorts, respectively, 30 and 10 oysters were placed at each location. Initial shell height and group weight were measured, then oysters were enclosed in mesh pouches and affixed inside shellfish bags to exclude predators. At the end of three months, survival, shell height and group weight were measured for live oysters.

Juvenile oyster survival was compared among bays and parental pCO_2 exposure with a binomial generalized linear mixed model (glmm) using `glmer` from the `lme4` package (vs. 1.1-

19). Chi-square tests compared survival differences among factors using the `car` package `Anova` function (Fox & Weisberg, 2011). Mean shell growth was determined by subtracting pre-deployment mean height from post-deployment mean height (not including dead oysters). Both mean shell growth and mass change were compared among factors using ANOVA and F-statistics to test differences by bay, parental pCO_2, and cohort.

Make and model details for instruments used during treatments and field deployments are available in the Appendix S1: Section S2. All data analysis was performed in R version 3.3.1 using the RStudio interface (R Core Team, 2016). Code for statistical analyses can be found in the associated Github repository (Spencer *et al.,* 2019).

Results

Adult reproductive development

After 60 days in temperature treatments (6.1±0.2°C and 10.2±0.5°C), gonad stage of the dominant sex differed significantly between temperatures (Table 2). The 10°C oysters had more instances of advanced gametogenesis (stage 2), and fewer that were resorbing/spawned (stage 4) (Figure 3). This difference was influenced strongly by more advanced male gametes in 10ºC oysters, but there were no differences in female gamete stages. No differences in sex ratio were observed between temperature treatments (Figure 4).

After 52 days in pCO_2 treatments, gonad stage of the dominant sex differed significantly between ambient and high pCO_2 in the oysters previously held in 10°C (Table 2). More mature gametes (stage 3) were found in 10°C-ambient pCO_2 (49%) compared to 10°C-high pCO_2 (33%). This difference was strongly influenced by oysters that were predominantly male, as male

gamete stage tended to differ between pCO_2 treatment, but female gamete stage did not (Table 2, Figure 3). In 6°C-treated oysters, there were no pCO_2 effects on gonad stage of the dominant sex, male gamete stage, or female gamete stage. No gonad stage or sex ratio differences were detected among oysters from 10°C-high pCO_2 (combined stressors) and 6°C-ambient pCO_2 (no stressors). Gonad sex did not differ significantly among treatments, however oysters tended to contain fewer male-only and more female-only gonad tissues in the riper, ambient pCO_2-treated groups than male-only tissues (Figure 4).

Compared to oysters before pCO_2 exposure, those exposed to high pCO_2 did not differ in gonad sex, stage of the dominant sex, or female gamete stage. Male gametes in the 6°C treated oysters developed while in the high pCO_2 exposure, but there was no change in the 10°C treated oysters. Oysters held in ambient pCO_2 had significantly more advanced gonad compared to before CO_2 exposure regardless of temperature, again influenced strongly by changes in male gamete stage (Table 2).

No sampled oysters contained brooded embryos or larvae. Gonad data and patterns within cohorts is reported in Appendix S1: Figures S3, S4, and Table S4.

Larval production

Adults exposed to 10°C produced more larvae on a daily basis (excluding days where no larvae were released) than those exposed to 6°C in ambient pCO_2-exposed oysters ($p=0.040$), but not in high pCO_2-exposed oysters ($p=0.66$) (Figure 6, pCO_2:temperature interaction: ($F(2,8)=5.1$, $p=0.037$). Total larvae released over the 90-day spawning period tended to differ by treatment, but not significantly (temperature:pCO_2 interaction ($F(2,8)=4.0$, $p=0.063$). Temperature and pCO_2 as single factors did not affect total larvae released or daily averages.

The date of first larval release differed by temperature regardless of pCO_2 (Figures 5 & 6, F(1,8)=11.9, p=0.0087), and pCO_2 had no effect on timing (not retained in model). Onset was on average 5.2 days earlier in the 10°C treatment. Timing of peak larval release also differed by temperature treatment regardless of pCO_2 (Figure 6, F(3,19)=6.7, p=0.018), occurring on average 8.3 days earlier in 10°C oysters. The 10°C treated oysters produced more large pulses of larvae, on average 2 additional days, than 6°C (F(1,8=7.25, p=0.027).

In total, 18.5 million larvae were collected from 767 oysters. Total larvae produced by each treatment was 3.1M, 4.8M, 5.9M, and 4.5M for 6°C-ambient pCO_2, 6°C-high pCO_2, 10°C-ambient pCO_2, and 10°C-high pCO_2, respectively. Based on reports of approximately 215,000 larvae produced per adult *O. lurida* of shell height 35 mm (Hopkins, 1936), the number of oysters that spawned as female in this study was approximately 86, with 14.3, 22.5, 27.6, and 21.0 from the 6°C-ambient pCO_2, 6°C-high pCO_2, 10°C-ambient pCO_2, and 10°C-high pCO_2 treatments, respectively. This estimate is likely low across all treatments, due to the smaller D and O-2 cohorts (mean length in F, D, O-1 and O-2 was 35.7 mm, 29.8 mm, 35.7 mm, and 20.0 mm, respectively), therefore the total number of oysters that spawned as female and released larvae is likely higher than 86.

Larval production and timing data, including differences among cohorts, are included in Appendix S1: Section S5 and Table S5.

Offspring survival in a natural setting

Juvenile survival after three months in the field was on average 15% higher in cohorts from high pCO_2 exposed parents than from ambient pCO_2 parents (44±37%, and 29±27%, respectively, χ^2=10.6, p=0.0011). The influence of parental pCO_2 on survival varied by bay (bay:parental

368 pCO_2 interaction χ^2=15.3, p=1.6e-3), and by cohort (cohort:parental pCO_2 interaction χ^2=23.5,
369 p=3.2e-5) (Table 3).

370 Survival in offspring from high pCO_2 parents was higher in the Fidalgo Bay and Port
371 Gamble Bay locations (χ^2=17.7, p= 2.6e-5; χ2=10.0, p=1.6e-3, respectively), but this was not
372 the case in Skokomish River Delta or Case Inlet. Survival in the F cohort was 38% higher in
373 oyster from pCO_2 parents than those from ambient pCO_2 parents across all deployment bays
374 (χ^2=28.1, p=4.6e-7), and within the Fidalgo Bay location (χ^2=17.6, p-adj=0.0001). Survival in
375 the D and O-1 cohorts did not differ significantly between parental pCO_2 across all bays (D:
376 χ^2=0.4, p=1, O-1: χ^2=2.5, p=0.44), or within individual bays. More O-2 juveniles with ambient
377 pCO_2 parents survived across all bays (χ^2=9.1, p=0.010), and within the Skokomish River Delta
378 (χ^2=8.9, p=0.011).

379 Without considering parental pCO_2, more oysters survived in Port Gamble Bay (mean
380 49±36%) and Fidalgo Bay (39±36%) than in Case Inlet (mean 29±29%, p=0.012 & p=0.037,
381 respectively) (bay factor, χ^2=18.5, p=3.4e-4). Survival at Skokomish River Delta did not differ
382 significantly from other locations (32±27%). No interaction between cohort and bay was
383 detected (χ^2=9.8, p=0.37) (Figure 7, Table 3).

384 Shell length was not affected by bay, cohort or parental pCO_2. The mass per oyster
385 (compared to before deployment) differed by cohort (F(3,76)=15.9, p=4.0e-8), due to Dabob Bay
386 cohort growing less than the other three cohorts (Δ g/oyster: D=0.5, F=1.2, O-1=1.6, & O-
387 2=1.0). Mass change also differed by bay (F(3,76)=4.8, p=3.9e-3) due to less growth in oysters
388 placed at Fidalgo Bay than in Port Gamble Bay and Case Inlet (Δ g/oyster: FB=0.7, PGB=1.0,
389 CI=1.1, SK=0.8) (Appendix S1: Figure S5).

Discussion

Ocean acidification and ocean warming potentially threaten marine organisms, particularly ectothermic calcifiers (Hoffman *et al.* 2010). An organism's genotype, complete environmental history, and the timing and magnitude of environmental perturbations may all determine its fitness in future ocean conditions. To begin teasing apart these complex factors in the Olympia oyster, this study examined four adult cohorts with distinct genetic structure but known, shared histories. Elevated winter temperature resulted in increased gonad development, which corresponded with earlier and more frequent larval release (on average 5.2 days earlier, 2 additional days). High pCO_2 exposure negatively influenced gonad maturation state, but did not affect subsequent fecundity. Offspring from parents exposed to elevated pCO_2 had higher overall survival upon deployment. Differences in juvenile survival among bays and cohorts indicate that carryover effects are dependent upon the environment and genotype, and reinforce the importance of using multiple sources of test organisms in stress-response studies.

Reproduction

We expected elevated winter temperature to reduce fecundity, based on predictions that changes to reproductive quiescence and metabolism would be deleterious to spring reproduction. Counter to this prediction, warm winter temperature positively affected larval production. Oysters in elevated temperature contained more developed male gametes after treatment, and subsequently began releasing larvae earlier and produced more larvae per day compared to cold-treated oysters. We find no evidence that cold winters are critical for spring reproduction, but rather elevated winter temperature may elongate the *O. lurida* spawning season. In comparison, a 29-year dataset of *M. balthica* reproduction showed that as winter temperature increased, spring spawning began earlier and fecundity declined (Philippart *et al.*, 2003). However, the present

413 study was conducted in a hatchery setting, with ample phytoplankton, and did result in a
414 temperature shift during spawning. In the wild numerous additional abiotic and biotic factors will
415 contribute to *O. lurida* fitness, and warmer winters may result in earlier and longer reproductive
416 seasons only if nutritional requirements are met. Whether larvae released earlier in the spring can
417 survive to recruitment will greatly depend on many factors including food availability and
418 predation. Those modeling larval recruitment (*e.g.* Kimbro, White & Grosholz, 2019; Wasson *et*
419 *al*., 2016) should consider including winter temperature as a factor influencing spatiotemporal
420 recruitment patterns.

421 We predicted that high pCO_2 exposure would redirect energy away from storage to
422 maintenance processes, resulting in delayed gametogenesis and poor fecundity in the spring.
423 After exposure to 3045 µatm pCO_2 (pH 7.31), fewer oysters contained ripe or advanced male
424 gonad tissue than in ambient pCO_2, signaling reduced spermatogenic activity. Female gonad, sex
425 ratios, and subsequent fecundity were not affected by sole exposure to high pCO_2. Similar
426 impacts on gametogenesis during exposure were observed in the Sydney rock (*S. glomerata*) and
427 Eastern (*C. virginica*) oysters, but with varying pCO_2 thresholds. Parker *et al.* (2018) found *S.*
428 *glomerata* gametogenesis to slow in 856 µatm (pH 7.91), and Boulais *et al.* (2017) found normal
429 rates at 2260 µatm (pH 7.5), delay at 5584 µatm (pH 7.1), and full inhibition at 18480 µatm (pH
430 6.9) in *C. virginica*. Together, these studies indicate that high pCO_2 slows the rate of
431 gametogenesis, but the level at which pCO_2 affects gametogenesis appears species-specific, and
432 likely reflective of variable physiological mechanisms and reproductive strategies.

433 The combined effects of sequential elevated temperature and pCO_2 treatments did not act
434 synergistically to delay gonad development, but instead resulted in oysters with gonad stage and
435 fecundity no different from the untreated oysters. Similarly, combined simultaneous temperature

436 and high pCO_2 exposures did not affect *S. glomerata* fecundity (Parker *et al.*, 2018). We did
437 detect a pCO_2 dependent effect of temperature on the average number of larvae released per day.
438 Oysters that had previously been exposed to 10°C produced more larvae than 6°C, but only after
439 ambient pCO_2 exposure, which may reflect a general reproductive arrest that occurs when
440 exposed to high pCO_2. Despite experimental differences (*e.g.* sequential vs. simultaneous
441 exposures) which can influence outcomes (Bible *et al.* 2017), both Parker *et al*. (2018) and the
442 present study indicate that high pCO_2 slows gametogenesis, elevated temperature accelerates it,
443 and these two environmental drivers act antagonistically on gonad development if occurring in
444 the same reproductive season. An important factor not included in either study is ecologically
445 relevant variability. Temperature and pCO_2 oscillations, driven by tides and diurnal
446 photosynthesis, could offer daily refuge or expose oysters to dynamic changes, altering how
447 combined stressors interact (Cheng *et al*. 2015).

448 In contrast to prior studies, temperature and pCO_2 did not impact *O. lurida* sex ratios,
449 whereas in high pCO_2 *C. virginica* skewed male (Boulais *et al.,* 2017), and *S. glomerata* skewed
450 female (Parker *et al.*, 2018). This observation may be explained by very low incidence of total
451 reproductive inactivity in our *O. lurida* cohorts — only four out of the 108 oysters that were
452 sampled prior to pCO_2 treatment contained empty follicles — and thus sex ratios may be
453 different if pCO_2 exposure occurs earlier in life during initial sex differentiation. Furthermore,
454 high pCO_2 exposure only occurred in winter, prior to spawning. If high pCO_2 persists during
455 oocyte maturation and spawning, *O. lurida* fecundity may be reduced similar to *C. virginica* and
456 *S. glomerata.* Future research should examine *O. lurida* sexual development during the initial
457 switch from male to female, which can occur the first winter after settlement (Moore *et al.*,

458 2016), and across a range of pCO_2 to determine conditions in which gametogenesis and sex
459 determination are affected.

460 **Offspring**

461 Abiotic parental stressors can be beneficial, neutral, or detrimental to offspring viability
462 (Donelson *et al.,* 2018). We explored carryover effects of adult exposure to winter pCO_2 on
463 offspring by testing survival in the field. Offspring with high pCO_2 parental histories performed
464 better in two of four locations, Fidalgo Bay and Port Gamble Bay. Carryover effects of parental
465 high pCO_2 exposure may therefore be neutral, or beneficial, to offspring depending on the
466 environmental conditions. Port Gamble Bay and Fidalgo Bay are more influenced by oceanic
467 waters, which could explain cooler observed temperatures. These locations are also typically less
468 stratified than the Skokomish River Delta and Case Inlet. In Port Gamble Bay, where pCO_2
469 parental history most significantly correlated with offspring survival across cohorts, mean pH
470 was considerably lower than the other deployment locations (-0.17 pH units), and mean salinity
471 was higher (+3.8 PSU). Given the experimental design we are able to clearly demonstrate that
472 manifestation of carryover effects in Olympia oysters is dependent on environmental conditions.
473 Specifically, there is a greater likelihood of beneficial carryover effects when parents are
474 exposed to stressful conditions. Overall, carryover effects of parental pCO_2 treatment were
475 positive, however negative effects were observed in the O-2 cohort. This discrepancy could
476 relate to unique O-2 juvenile characteristics, as they were bred from siblings, and were 3rd-
477 generation hatchery produced. The complex interactions among parental exposure, bay, and
478 cohort indicate that offspring viability is influenced by ancestral environment history,
479 environmental conditions, and genotype.

Our results contrast with a similar study that exposed *C. gigas* oysters to high pCO_2 during the winter, and found fewer hatched larvae 18 hours post-fertilization from exposed females, with no discernable paternal effect (Venkataraman, Spencer & Roberts, 2019). Hatch rate was not directly measured in this study due to the *O. lurida* brooding behavior; however, no difference in daily and total larvae released suggest that hatch rate was unaffected by pCO_2. The different responses seen in Venkataraman, Spencer & Roberts (2019) and the present study may reflect variability among species and spawning method. *C. gigas* gametes were collected artificially by stripping gonad, whereas *O. lurida* late-stage veliger larvae were collected upon release from the brood chamber. For instance, volitionally-spawned gamete quality and fertilization rates could vary between the natural versus artificial settings to influence larval viability. Larval brooding may also be a mechanism by which sensitive larvae are acclimatized to stressors, as the *O. lurida* brood chamber pH and dissolved oxygen can be significantly lower than the environment (Gray *et al*., *in press*).

Beneficial parental carryover may also be linked to the male-specific gonad effects, and the conditions in which the adult oysters were held. During high pCO_2 exposure, oocyte stage and prevalence did not change, which indicates that oogenesis did not occur. Negative intergenerational carryover effects are commonly linked to variation in oocyte quality, which can be affected by the maternal environment during oogenesis (Utting & Millican, 1997). In the Chilean flat oyster (*Ostrea chilensis*), for instance, egg size and lipid content positively correlate with juvenile growth and survival (Wilson, Chaparro, & Thompson, 1996). If high pCO_2 exposure were to coincide with oocyte proliferation and growth, *O. lurida* egg quality and larval viability could be compromised. In contrast, male gonad stage advanced significantly during pCO_2 exposure. Intergenerational and transgenerational carryover effects are increasingly linked

503 to the paternal environment in other taxa, such as inheritance of epigenetic changes to the male
504 germ line (Rodgers, Morgan, Bronson, Revello, & Bale, 2013; Anway, 2005; Soubry, Hoyo,
505 Jirtle, & Murphy, 2014). Positive carryover effects of environmental stressors observed in this
506 and other marine invertebrate taxa may be due to paternal epigenetic effects, but this link has not
507 yet been observed.
508

509 # Conclusion

510 This study clearly demonstrates that exposure to elevated winter temperature and altered
511 carbonate chemistry impacts reproduction and offspring viability in the Olympia oyster.
512 Furthermore, we report the first observations of intergenerational plasticity in an *Ostrea* species,
513 that is dependent on offspring environmental conditions and population. The observed context-
514 dependent carryover effects could have a substantial impact on species resilience. Combined
515 with previous reports of resilience to environmental stressors (Waldbusser *et al* 2016; Cheng *et*
516 *al.* 2017) and intraspecific variability (Bible, Evans & Sanford, 2019; Maynard, Bible, Pespeni,
517 Sanford, & Evans, 2018; Silliman, Bowyer, & Roberts, 2018; Heare, Blake, Davis, Vadopalas, &
518 Roberts, 2017), the Olympia oyster may be more capable than other marine bivalve species to
519 withstand and adapt to unprecedented ocean change. Furthermore, conserving and restoring *O.*
520 *lurida* in a variety of settings — including hypoxic, warmer, and less alkaline areas — could
521 increase the probability that future populations are equipped for challenging conditions through
522 selection or intergenerational carryover.
523 As temperatures rise and ocean acidification progresses, there may be profound and
524 unexpected seasonal changes across marine taxa. Accurate predictions will need to consider
525 parental carryover effects, as they can impart neutral, beneficial, or detrimental characteristics to

offspring, which depend on complex interactions among parental exposure timing, reproductive strategies, species plasticity, and standing genetic structure. With these considerations, future biological response studies need to be aware of three possible factors influencing results: 1) source population; 2) environmental history (within-lifetime carryover effects); and 3) ancestral environmental history (inter- and transgenerational carryover effects). Controlling for, or at minimum recognizing and recording these factors, will provide important context for those predicting ecosystem response to environmental change.

Acknowledgements

Our gratitude to the following people who assisted with this project: Grace Crandall, Kaitlyn Mitchell, Olivia Smith, Megan Hintz, Rhonda Elliott, Lindsay Alma, Duncan Greeley, Beyer and Jackson Roberts, and Ian Davidson helped with oyster husbandry and sampling; Alice Helker advised on husbandry and larval rearing system engineering; Emily Kunselman helped manage the field deployment; Sam White and Hollie Putnam contributed to the carbonate chemistry analysis; Katherine Silliman and Jake Heare produced (and saved) the experimental oysters; the NOAA Manchester Research Center and Puget Sound Restoration Fund provided facilities and materials; committee members Jackie Padilla-Gamiño and Rick Goetz advised and supported this extended project. Thank you to David Kimbro and an anonymous reviewer for constructive comments on the manuscript.

Chlorophyll (µg/L)	2.27±4.09	2.25±1.45	5.72±15.36	3.31±6.13

Table 2: Gonad stage and sex comparisons among treatments. Gonad was sampled after temperature treatment but before pCO_2 (6°C Pre and 10°C Pre, n=54), and after pCO_2 treatment (Amb=841±85 µatm, n=39; High= 3045±488 µatm, n=39). Pearson's chi-square statistics are shown with p-adj in parentheses for gonad sex, stage of the dominant sex, male gametes when present, and female gametes when present. Cells with * and in bold indicate significant differences between comparison; blank cells=not tested; % of mature = % of sampled oysters that contained stage 3 male or female gametes, per treatment.

Table 3: Offspring survival in the field. 1-year old juveniles were deployed for 3 months in four bays in Puget Sound, Washington, in 2 sites per bay. Percent survival ± SD is shown by cohort x bay x parental pCO_2 treatment (Amb=841±85 µatm, High= 3045±488 µatm). Only offspring from 6°C-treated adults were deployed. Significant survival differences were detected between parental pCO_2 treatment within the Fidalgo Bay and Oyster Bay F2 cohorts (*), and across all cohorts (+).

844 **Figure 1**: Locations where *O. lurida* populations' progenitors were collected (F, D, O), where
845 oysters were housed prior to and during the experiment (C), and where offspring were deployed
846 (F, P, S, I): Fidalgo Bay (F), Port Gamble Bay (P), Dabob Bay (D), Clam Bay (C), Skokomish
847 River Delta (S), Case Inlet (I), Oyster Bay (O).

848 **Figure 2**: Experimental timeline. Four cohorts of adult *O. lurida* (F, D, O-1, O-2) were
849 sequentially exposed to two winter temperatures (6.1±0.2°C, 10.2±0.5°C) then two pCO_2 levels
850 (841±85 µatm, 3045±488 µatm). They were returned to ambient pCO_2 conditions to volitionally
851 spawn. Larvae were collected and reared by cohort x temperature x pCO_2. Juveniles (~1 year)
852 from 6°C-Ambient pCO_2 and 6°C-Low pCO_2 adults were deployed in 4 bays in Puget Sound.

853 **Figure 3**: Gonad developmental stages for male and female gametes, after 60-days in
854 temperature treatments but before pCO_2 treatments ("Pre", n=54) and after 52 days in high pCO_2
855 (3045±488 µatm, n=39) and ambient pCO_2 (841±85 µatm, n=39), which indicates that sperm
856 development was influenced by elevated winter temperature (more advanced) and high pCO_2
857 (less advanced, 10°C treatment only), but oocyte development was not. All oysters were
858 assigned both male & female stages; if no oocytes were present, for example, that oyster was
859 designated as female stage 0.

860 **Figure 4**: Gonad sex, after 60-days in temperature treatments but before pCO_2 treatments ("Pre",
861 n=54) and after 52 days in high pCO_2 (3045±488 µatm, n=39) and ambient pCO_2 (841±85 µatm,
862 n=39). Winter conditions did not significantly influence gonad sex ratios.

863 **Figure 5:** Cumulative larvae released over 90 days of continuous volitional spawning under
864 hatchery conditions, normalized by the number of adult oysters. Each of the four panels represent
865 a cohort, and lines are color coded by winter temperature and pCO_2 treatments, where ambient

866 pCO_2 = 841 µatm (7.8 pH), and high pCO_2 = 3045 µatm (7.31). Reproductive conditioning and
867 spawning occurred at 18°C, in ambient pCO_2, and with live algae at a density of 66,000 ± 12,000
868 cells/mL.

869 **Figure 6:** Left: average number of larvae collected on a daily basis (excluding days where no
870 larvae were released). Daily pulses of larvae were larger in 10°C than 6°C, but only in oysters
871 exposed to ambient pCO_2. For statistical analysis, data was normalized by number of oysters *
872 average oyster height (cm) (data shown is not normalized). Right: number of spawning days until
873 larval release peaked; peak release occurred on average 8.3 days earlier in 10°C treated oysters.
874 Letters (a, ab, b) indicate differences among treatments. Boxes contain values lying within the
875 interquartile range (IQR), with medians indicated by lines in the middle of boxes. Whiskers
876 extend to the largest value no greater than 1.5*IQR.

877 **Figure 7:** Percent survival of juvenile offspring in the field. The four panels each represent
878 survival in one bay (Fidalgo Bay, Port Gamble Bay, Skokomish River Delta, Case Inlet). Within
879 each panel, boxplots are separated by parental pCO_2 exposure (Ambient=841 µatm, High=3045
880 µatm). Points indicate % survival in each deployment pouch, and symbols indicate cohort
881 (Fidalgo Bay, Dabob Bay, Oyster Bay Cohort 1, and Oyster Bay Cohort 2). Letters (a, b) indicate
882 survival differences among parental pCO_2 exposure within each bay. Boxes contain values lying
883 within the interquartile range (IQR), with median survival indicated by lines in the middle of
884 boxes. Whiskers extend to the largest value no greater than 1.5*IQR.
